Investigation into the reasons for preventable drug related admissions to a medical admissions unit: observational study

R L Howard, A J Avery, P D Howard, M Partridge

Objective: To describe the drugs and types of medicine management problems most frequently associated with preventable drug related admissions to an acute medical admissions unit.

Design: Observation study.

Setting: Medical admissions unit in a teaching hospital in Nottingham, UK.

Participants: 4093 patients seen by pharmacists on the medical admissions unit between 1 January and 30 June 2001.

Main outcome measures: Proportion of admissions that were drug related and preventable, classification of the underlying causes of preventable drug related admissions, and identification of drugs most commonly associated with preventable drug related admissions.

Results: Of the admissions seen by pharmacists, 265 (6.5%) were judged to be drug related and 178 (67%) of these were judged to be preventable. Preventable admissions were mainly due to problems with prescribing (63 cases (35%)), monitoring (46 cases (26%)), and adherence to medication (53 cases (30%). The drugs most commonly implicated were NSAIDs, antiplatelets, antiepileptics, hypoglycaemics, diuretics, inhaled corticosteroids, cardiac glycosides, and beta-blockers.

Conclusions: Potentially preventable drug related morbidity was associated with 4.3% of admissions to a medical admissions unit. In 91% of cases these admissions were related to problems with either prescribing, monitoring, or adherence.

METHODS

Selection of participants

The local research ethics committee approved the study. All patients admitted to the medical admissions unit (box 1) and seen by a pharmacist between 1 January and 30 June 2001 were included in the study. The pharmacists saw patients as part of their routine work Mondays to Fridays. They recorded details of all patients seen and reported patients with any suspected drug related morbidity to the principal investigator.

Box 1 Description of the Medical Admissions Unit at Queens Medical Centre, Nottingham

The medical admissions unit at Queens Medical Centre (QMC), Nottingham is a 30 bed unit which receives acute medical admissions from general practitioners and the A&E department. A small number of admissions come from other hospitals or wards within the QMC (these were not included in the study). The ward is covered Monday to Friday by three admissions ward pharmacists (all have a clinical diploma) between 07.00 and 19.00 hours. The pharmacists are responsible for checking the medication histories of patients admitted (by reviewing patients’ own medication, questioning patients, contacting general practice surgeries and nursing homes, etc), as well as supplying medication and ensuring the safety of the prescribing on the unit. Part of this role inevitably involves identifying drug related morbidity. There are two consultant-led multidisciplinary ward rounds each day (morning and evening) which are attended by one of the admissions unit pharmacists. Over-night and at weekends the admissions unit is covered by a limited pharmacy service.

Recent reports in the USA and the UK highlight the problem of drug related morbidity and the need to find ways to prevent medical errors. These reports suggest that preventable drug related admissions require particular attention and, in 2002, two systematic reviews were published on this topic.1,2 Winterstein et al3 identified 15 studies of preventable drug related hospital admissions and found a median of 7.1% of admissions to be drug related, and 59% of these to be preventable. Beijer et al4 reviewed 68 studies, 12 of which looked at preventable admissions. This review highlighted some of the limitations of previous research and emphasised the need for further studies looking at the preventability of drug related admissions and documentation of the drugs responsible for these admissions. This sort of information is needed if we are to develop effective strategies to prevent drug related admissions. In addition, it is important to identify some of the underlying causes of preventable admissions.

We have addressed some of these issues by conducting a large study of drug related morbidity detected by pharmacists on a medical admissions unit in the UK. We have defined drug related morbidity as adverse drug reactions, failure to optimise treatment, unintentional overdose, and adherence problems. Admissions associated with intentional overdoses and drugs of abuse were excluded.

The objectives of our study were to:

- estimate the proportion of admissions to an acute medical admissions unit that were associated with drug related morbidity and the proportion of these admissions that were potentially preventable;
- identify the drugs associated with the preventable drug related admissions;
- classify preventable drug related admissions by the underlying causes—for example, prescribing problems, monitoring problems, adherence problems and supply problems.
Following discharge from hospital, the principal investigator assessed possible cases using a combination of:

- medical note review (throughout the admission and on discharge);
- contact with general practitioners, where necessary, to obtain medication histories, test results, and information regarding the management of patients in primary care;
- interviewing patients, where possible, about the type and duration of symptoms and medication use, using an interview schedule. Those not interviewed included patients discharged home before being seen by the principal investigator, patients too unwell to be interviewed, and patients unable to speak English.

Following assessment by the principal investigator, some cases were excluded from further review (fig 1). These included cases where further investigation suggested that drug related morbidity was unlikely—for example, a low probability VQ scan in a case of suspected pulmonary embolism in a woman taking a combined oral contraceptive. In order to ensure that some patients were included in the study who had been admitted at weekends, the principal investigator identified patients with potential drug related morbidity through medical note review and patient interview on alternate weekends (fig 1).

**Classification of potential drug related admissions**

Following discharge from hospital, the principal investigator prepared detailed case summaries on patients with suspected

(RH). Similar methods have been used successfully in at least five previous studies.10

The principal investigator assessed possible cases using a combination of:

- medical note review (throughout the admission and on discharge);
- contact with general practitioners, where necessary, to obtain medication histories, test results, and information regarding the management of patients in primary care;
- interviewing patients, where possible, about the type and duration of symptoms and medication use, using an interview schedule. Those not interviewed included patients discharged home before being seen by the principal investigator, patients too unwell to be interviewed, and patients unable to speak English.

Following assessment by the principal investigator, some cases were excluded from further review (fig 1). These included cases where further investigation suggested that drug related morbidity was unlikely—for example, a low probability VQ scan in a case of suspected pulmonary embolism in a woman taking a combined oral contraceptive. In order to ensure that some patients were included in the study who had been admitted at weekends, the principal investigator identified patients with potential drug related morbidity through medical note review and patient interview on alternate weekends (fig 1).

**Classification of potential drug related admissions**

Following discharge from hospital, the principal investigator prepared detailed case summaries on patients with suspected drug related admissions (fig 1). The principal investigator identified patients with drug related admissions and patient interview on alternate weekends (fig 1). Patients were included in the study who had been admitted at weekends, the principal investigator identified patients with drug related admissions and patient interview on alternate weekends (fig 1).

**Box 3 Criteria used to review possible drug related admissions cases**

**Amended Hallas criteria for causality**

1. Known adverse drug reaction, toxic reaction, response to omission of treatment or inadequate treatment.
2. Reasonable temporal relationship between commencement or cessation/omission of treatment and onset of problem.
3. Risk of further problems likely to be reduced by dose reduction or increase, discontinuation, closer monitoring or commencement of treatment.
4. Not explained by any other known condition predisposing to the patient, or this condition/predisposition is likely to be exacerbated by the presence/absence of the drug.
5. For drug toxicity:
   - symptoms re-appeared upon re-exposure;
   - laboratory tests showed toxic drug levels or drug induced metabolic disturbances that explained the symptom;
   - symptoms resolved on dose reduction or discontinuation of the drug.
   For drug omission:
   - symptoms resolved upon re-introduction of the drug or dose increase.

If 5 criteria fulfilled then definite.
If 4 criteria fulfilled then probable
If 3 criteria fulfilled then possible
If 2 or less criteria fulfilled then either, not drug related or unvaluable

**Hepler criteria for preventability**

1. Drug related morbidity (DRM) preceded by a recognisable drug therapy problem (DRP).
2. Given the DRP, the DRM would have been reasonably foreseeable.
3. The cause of DRM would have been identifiable with reasonable probability (Hallas criteria probable or definite for causality).
4. The cause of the DRM could have been reasonably controllable within the context and objectives of treatment.

All four criteria must be fulfilled to confirm preventability.

**Contribution of drug related problem to hospital admission**

Score = 3 (dominant): the suspected symptoms were the main reason for admission and no other symptoms contributed significantly.
Score = 2 (partly contributing): the suspected symptoms played a substantial role in admission, but other factors also contributed significantly.
Score = 1 (less important): the suspected symptoms played a minor or uncertain role, and the patient would probably have been admitted without them.
Score = 0 (not contributing): other symptoms/circumstances were the reason for hospitalisation.

**Hepler definitions for classification of drug related admissions**

Score = 1: inappropriate prescribing.
Score = 2: inappropriate delivery (unavailable when needed, inappropriate formulation, failure to administer, dispensing error).
Score = 3: inappropriate behaviour by the patient (non-compliance).
Score = 4: patient idiosyncrasy (response to drug, mistake, or accident).
Score = 5: inappropriate monitoring.
Score = 6*: potentially preventable with interventions which are not standard care at present.

*Category 6 is additional to the original Hepler classification
drug related morbidity (box 2). These summaries provided reviewers with information on temporal relationships between medications and symptoms, the nature of patients’ symptoms, medication changes resulting from the admission, and the diagnoses made by physicians caring for the patients. The case summaries were independently scored by a hospital physician (PH), an academic general practitioner with a special interest in prescribing (AA), and a clinical pharmacist (RH). Each reviewer scored the cases using explicit criteria for causality,1 preventability,3 contribution to the admission,1 and classification of the underlying cause of the drug related morbidity2 (box 3). All the criteria were validated in pilot study work where 46 possible cases of drug related morbidity were reviewed to ensure the criteria were reliable and gave reasonable agreement between the reviewers. After scoring the cases the reviewers met up and, in keeping with standard practice in this field,1 a majority decision was used to classify the cases where there was disagreement on any of the review criteria.

Admissions were classified as drug related if two or more reviewers scored 4 or 5 using the amended Hallas criteria and judged the drug to have made a dominant or partial contribution to the admission. Admissions were classified as potentially preventable if the above criteria were fulfilled and two or more reviewers scored 4 using the Hepler criteria for preventability.

Recording of data
For all admissions to the medical admissions unit age, sex, and date of admission were recorded on an ACCESS 97 database. The hospital routinely records details of primary diagnoses of patients admitted, classified according to the International Classification of Diseases and Related Health Problems, 10th revision.11 These data were available for 7962 (91%) of all patients admitted (Table 1). The data were exported to SPSS version 10.0 for statistical analysis and were grouped by British National Formulary codes.

Analysis of data
Data were exported to SPSS version 10.0 for statistical analysis. To assess differences between the groups of patients seen and not seen by a pharmacist, patient characteristics were compared using an independent t test for age on admission and χ² tests for sex, day of admission, and primary diagnosis (available for 7962 (91%) of all patients admitted). To assess inter-reviewer reliability, case review scores were compared using Cohen’s kappa and intraclass correlation coefficients (moderate to substantial agreement is indicated by kappa 0.41–0.80).15 The proportion of patients considered to have a drug related admission was calculated as the percentage of patients seen by a pharmacist who were classified as having definite or probable drug related morbidity that had made a dominant or partial contribution to the admission. We also calculated the proportion of drug related admissions that were considered potentially preventable. The proportion of patients considered to have a potentially preventable drug related admission was calculated as the percentage of patients seen by a pharmacist who were judged to have a preventable drug related admission.

RESULTS
Patient characteristics
The flow of patients through the study is shown in box 2. Of the 8781 patients admitted to the medical admissions unit, 4093 (47%) were seen by a pharmacist. The mean (SD) age of patients seen was 62.6 (20.7) years and the mean (SD) age of patients not seen by a pharmacist was 62.0 (20.6) years. Of the patients seen by a pharmacist 2002 (49%) were female and 2289 (49%) were male.

Comparing patients who were either seen or not seen by a pharmacist, there were no significant differences in age...
In recent years there have been calls for researchers to move beyond simply reporting preventable adverse events to finding ways of improving patient safety through avoidance of these events. It has been suggested that an approach focusing on systems failures is likely to be most effective. The key to starting this process is to find out which types of problem are the key to preventing these events.

In order to minimise the risk of misclassifying cases, we used a methodology which compares well with the most rigorous studies previously reported. We used explicit criteria to guide the assessment of cases and a three member panel of reviewers to independently classify each case. Despite the varied backgrounds of the reviewers, kappa and intraclass correlation coefficients showed good to excellent levels of agreement. Only those admissions where the drug related morbidity was judged to be the dominant cause, or partially contributing, to the admission were included as drug related admissions. Also, when we classified drug related admissions as preventable, it was our view that the problems identified were predictable and controllable in terms of the treatment (Box 4). Nevertheless, our results could be questioned in terms of the extent to which they reflect the true preventability of the observed outcomes. For example, a recent study of hospital deaths that were attributed to medical error suggested that in many cases the error made relatively little difference to expected fatal outcomes in seriously ill patients. While these results are not directly comparable to our study, we recognise that some of the patients in our study were at very high risk of hospital admission regardless of any preventable medication related adverse event.

In our study we reviewed only those patients seen by a pharmacist on the admissions unit. This means that our estimates of the proportion of admissions that were drug related and preventable need to be treated with some caution. The patients we studied were not fully representative of all patients admitted. However, the differences between the groups seen and not seen by a pharmacist were relatively small and, had we studied all the admissions, it is unlikely that the results would have been substantially different. In addition, our findings were similar to median figures from a recent systematic review.

Almost 60% of the preventable drug related admissions that we found are shown in tables 3–5. These data describe the drugs most commonly associated with admissions. We have recently completed a systematic review of interventions aimed at improving prescribing practice.
at reducing medication related morbidity in primary care.\textsuperscript{21} Combining evidence from this review with results from the study presented here means that we are able to suggest the types of interventions that may be most successful in reducing the incidence of preventable drug related admissions.

In terms of prescribing related problems, our study suggests that it may be worth focusing on preventing morbidity associated with NSAIDs and antiplatelet drugs. We know that it may be worth focusing on preventing morbidity associated with NSAIDs and antiplatelet drugs. Many of the problems identified in this study arise from co-prescription with ulcer healing drugs can reduce the risk of gastrointestinal bleeds and educational interventions have been shown to improve the safety of GP prescribing.\textsuperscript{23–25} Indeed, in a large Australian study an educational intervention focusing on NSAIDs reduced by 70\% the rate of hospital admissions for upper gastrointestinal ulceration, bleeding and perforation.\textsuperscript{21} In terms of monitoring, some of the best evidence for improvements in primary care relate to the monitoring of warfarin.\textsuperscript{26–30} The results of these studies may not be applicable to other drugs, but they suggest that nurse led monitoring clinics,\textsuperscript{27–28} computerised decision support systems,\textsuperscript{27–28} patient education and involvement,\textsuperscript{29} and patient self-management\textsuperscript{29–31} may help to improve control through improved monitoring. In our systematic review\textsuperscript{21} we did not find many other studies that looked at medication monitoring in primary care, and we believe that there is a need for further research in this area.

In terms of patient adherence, a number of studies have shown that improved education\textsuperscript{32} and approaches that provide greater involvement of patients in decision making\textsuperscript{32} improve patient adherence and may reduce drug related admissions. However, few studies have attempted to show clinical benefits.\textsuperscript{33} Our study suggests that priority should be given to patients taking the drugs listed in table 5.

Many of the problems identified in this study arise from medicines management in primary care, but it should be recognised that drug related admissions are relatively rare from the primary care perspective.\textsuperscript{35} For example, while NSAIDs were responsible for 12.4\% of potentially preventable admissions in

our study, a German study estimated that NSAIDs were associated with just 5.5 hospital admissions per 10 000 patients treated with these drugs in primary care. This may have important implications for encouraging general practitioners and health service managers that drug related admissions are important enough to justify potentially significant changes in medicines management. The types of changes outlined above could mean increased costs associated with gastroprotection for patients taking NSAIDs, more frequent monitoring for patients on medicines management. The types of changes outlined above could be of importance for encouraging general practitioners and health service managers that drug related admissions are important enough to justify potentially significant changes in medicines management.

ACKNOWLEDGEMENTS
The authors thank Chris Love for providing the original idea for this study and for identifying the patients; Judy Cantrell and Caroline Morris, Almune Winterstein and Doug Hepler for advice on study design; Simona Brackenborough, Gail Marlow and Louise Brown for identifying the patients; Sarah Rodgers and James Turton for their help with the database; Karen Neil for helping to develop the review criteria; Michael Dewey and Simon Royal for statistical advice; Barry Fuertado from medical records for finding patient records after discharge; IM&T at University Hospital, Nottingham for providing admissions data; and general practitioners, practice staff and patients for their contributions.

Funding: This study was part funded by Wyeth Laboratories and part funded by NHS R&D.

AA conceived the study and was responsible for the design along with RH and MP. RH collected all the data and produced all the case summaries needed for the study. RH, AA and PH reviewed all of the cases. RH processed the data, entered it on to computer and analysed it with help from AA. All of the authors were involved in the interpretation of the results. RH and AA wrote the paper with PH and MP providing critical comments.

Expanded versions of tables 3, 4 and 5 are available on the QSHC website at www.qshc.com/supplemental.
