Effectiveness Bulletin

Preventing falls and subsequent injury in older people

Ann Oakley, Merry France Dawson, Janet Holland, Sean Arnold, Colin Cryer, Yvonne Doyle, John Rice, Christine Russell Hodgson, Amanda Sowden, Trevor Sheldon, Deirdre Fullerton, Ann-Marie Glenny, Alison Eastwood

This paper is based on Effective Health Care, Vol 2, No 4, which is a systematic review of the evidence for the effectiveness of interventions to prevent falls and subsequent injury in older people. The relevant literature was identified by a search of several computerised databases (Social Science Citation Index (BIDS), PSYCHLIT, EMBASE, RCN database, AMED, and UNCOVER), citation in identified papers and previous reviews, and contributions from peer reviewers and other experts in the field. Only randomised controlled trials evaluating the effectiveness of preventive interventions which measured the effect on falls, injuries related to falls, or change in a risk factor for falls were included.

Background

In 1991 in the United Kingdom about one in six people were over 65 years of age, and by 2021 this proportion is expected to be nearly one in five. Accidents are a major health problem among older people with falls, traffic accidents, and burns the main causes of accidental death. Of these categories, falls are the leading cause of death from injury among people aged over 75 and over 85% of all fatal falls in the home in England and Wales are in people aged over 65. About one third of the population over 65 years of age and more than half of the women over 85 years living at home (and a greater proportion of those in institutional settings) will fall at least once every year. Reducing the death rate from accidents in people aged 65 and over by at least 33% by the year 2005 is a specific target in the United Kingdom Department of Health’s strategy Health of the Nation.

Identifying older people at risk

There are many epidemiological studies which have identified several potential risk factors for falls. At present, however, there is no agreed and reliable set of risk factors for falls and subsequent injury, although it is widely recognised that the causes of falls are often multifactorial. Some of the most often cited potential risk factors are nutritional status such as vitamin D and calcium deficiency; environmental hazards such as loose carpets in the home; prescribed medications; lack of exercise (associated with weak muscles and poor balance) and age related changes such as a deterioration in vision.

Effectiveness of interventions to reduce the risk of falling

EXERCISE

The question of whether short term exercise reduces falls in older people has been specifically considered in the frailties and injuries cooperative studies of intervention techniques (FICSIT) programme of randomised controlled trials in the United States. Two of the trials were carried out in nursing homes and five were community based and participants had to be at least 60 years of age. Seven of the trials included an exercise component, for a duration of 10-24 weeks, which was sometimes combined with other interventions. Participants were followed up from two to four years after the intervention (table 1).

In a meta-analysis of these trials, participants who were assigned to exercise groups had an estimated 10% lower risk of falling than controls (adjusted fall incidence ratio (IR)=0.90; 95% confidence interval (95% CI) 0.81-0.99; P=0.04). When the results from trials in which balance training was the only intervention, were pooled, a 25% reduction in the risk of falling was found (IR=0.75, P=0.01). In one trial of community dwellers of average age 75 those receiving Tai Chi classes (a balance exercise) had a 37% lower risk of falling than the control group (IR=0.63; 95% CI 0.44-0.89).

Because the study participants were generally healthier and better educated than average it is not clear whether the results could be generalised to a typical older population. One of the trials, for example, which evaluated balancing and resistance exercises in an unrepresentative healthy and well off group of older people found no effect of the intervention.

Table 2 shows the results of other randomised controlled trials which have evaluated exercise only interventions in the prevention of falls. In one study, where the aim

To determine whether, in older community dwellers, exercise and cognitive behavioural interventions can improve balance, reaction time, and lower extremity muscle strength, the rate of falls was found to be higher (although not significantly) in groups receiving low-intensity exercise. In another study no significant effect on falls was detected overall, although there was a significant drop in falls due to loss of balance. In a third study balance training was found to reduce the rate of falls in platform sensory tests.

Thirteen randomised controlled trials were identified which evaluated the modifying effect of exercise interventions on potential risk factors for falls.

factors for falling. Seven studies showed a decrease in risk factors for falls with exercise,24-31 four showed no significant effect other than improvements in strength,32-35 one showed an improvement in flexibility,36 and one reported a deterioration in postural sway with exercise.37

Overall, despite the variable quality of these studies, their results together with the results from the FICSIT trials provide reasonable evidence to suggest that exercise may help reduce the risk of falls and some risk factors for falls. Those interventions which use balancing exercise, strength training, and low impact aerobic exercise may be the most effective.

COST AND BENEFITS OF EXERCISE
An increase in physical activity is likely to have other benefits for older people. A meta-analysis has shown that exercise can reduce the risk of coronary heart disease.38 A recent review of the healthcare costs and benefits of exercise reported that in people over 45 years of age, exercise results in savings in the cost of health care by reducing in morbidity from coronary heart disease, falls, etc.39 However, the type of exercise must be appropriate to the level of health and fitness of the person. A recent review of trials evaluating the effectiveness of methods to promote exercise in community-based adults (of which some studies were in people over 55 years of age) concluded that it is possible to both increase and maintain levels of activity. This is best achieved when exercise is of moderate intensity, can be performed either alone or with others, is enjoyable and convenient, and can be completed in three sessions a week. Professional support or interaction with a healthcare professional seems to be important in promoting exercise and adherence.40

HOME ASSESSMENTS AND SURVEILLANCE
Table 3 shows the results of randomised controlled trials which have evaluated home assessment and surveillance interventions.17-48 All studies involved visiting older people at home, assessment of the safety of the home environment, followed by a range of interventions such as safety checks and necessary modifications, referral to care, and recommendations for exercise. All these studies took place in North America except for one in the United Kingdom.45

In one study, which included over 2000 people, it was found that participants who were offered a home intervention to remove and repair safety hazards showed a reduction in falls compared with controls.47 Similarly, in a study in which the intervention involved trained volunteers visiting older people at home, one third of the number of falls were reported compared with controls.48 A multifactorial intervention with home visits from nurses was also associated with a reduced number of falls in the first year of follow up.48 However, this effect was not sustained at two years, suggesting that the effects may be lost if the intervention is discontinued. In another multifactorial intervention in which nurses and physiotherapists were responsible for implementation, interventions were tailored to individual risk factors such as multiple drug use, use of sedatives or hypnotics, postural hypotension, etc. The rate of reported falls was reduced by 21%.17 The two other large trials did not find any effect of home assessment on the rate of falls.44 45

Effectiveness of interventions to reduce injury from falls

Dietary interventions
Reduced concentrations of vitamin D are associated with increased bone loss, an important risk factor for bone fractures, especially in older women. Vitamin D is one of several agents which can reduce bone loss in healthy postmenopausal women, particularly in the winter49 and may therefore reduce the risk of fractures in those who fall.

A recent Cochrane Collaboration systematic review50 found two large randomised controlled trials which assessed the effect of oral vitamin D and calcium supplements on frail women in nursing homes51 and oral vitamin D alone.52 Vitamin D given with calcium in doses between a quarter to a third higher than the current United Kingdom recommended daily allowances seemed to reduce the number of people who had one or more fractures by 20% over a three year period (P<0.02).11 However, when given in lower doses, vitamin D by itself did not show a protective effect.52 The only trial to evaluate vitamin D given as an annual injection reported a significant drop in the fracture rate.19 However, this study was not properly randomised, but points to the need for replication in a better trial. The review also showed that dietary calcium supplement alone may be effective in reducing symptomatic fractures (OR = 0.37; 95% CI 0.4 -0.97).55

This review shows that there is potential to prevent fractures in older people with vitamin D, or calcium, or both. One possible way to implement this intervention would be to promote exposure to sunlight and increased consumption of dairy products. However, dietary supplements in older people at high risk of fractures may be a more effective option.54

Hip protectors
A Danish randomised controlled trial evaluated the use of external hip protector pads to prevent injury from falls in people in residential nursing homes aged 69 years and over (table 4). The risk of a hip fracture in those wearing hip pads was more than halved (age adjusted risk ratio (RR) = 0.4; 95% CI 0.18 - 0.82).56 No fractures occurred in anyone wearing the pads at the time of a fall. Although, this seems a promising intervention in those at high risk of a fall the extent to which protection pads are generally acceptable and would be worn by older people living in the community is unclear. One of the FICSIT trials is designed to explore the acceptability of hip protectors in community and residential settings.54

Conclusions

Balancing, low impact aerobics, and muscle strengthening exercise may reduce the rate of falls in older people with reasonable levels of fitness. Research is needed to identify the most cost effective exercise programmes which could, for example, explore ways of promoting uptake and long term adherence, and evaluate the relative advantage of different types of exercise.

Home visiting to identify and remedy environmental and personal risks of falling may also reduce the risk of falling. The changes could include removal of throw rugs and objects in pathways, and the installation of improved night lights and bath non-skid mats. These changes could be carried out by health visitors, nurses, occupational therapists, or trained volunteers. Further research on applying this in the United Kingdom is needed.

High dose vitamin D supplements with or without calcium seem to be effective in reducing risk of fracture, although major trials to assess the cost effectiveness of vitamin D and calcium supplements are needed. In particular, the potential value of an annual vitamin D injection should be explored.

The use of hip pad protectors for people in institutional care who are at high risk of falling may significantly reduce the rate of injury due to falls. Their acceptability in other settings needs to be evaluated.
