HEROES AND MARTYRS OF QUALITY AND SAFETY

Surgical experience, hospital size and severity adjusted mortality: James Y Simpson, 1869

D Neuhauser

Qual Saf Health Care 2005;14:67–68. doi: 10.1136/qshc.2004.013102

Do experienced surgeons have better outcomes? Is mortality lower in “the wards of our (large) palatial hospitals”? To make such comparisons of outcomes of care between providers, it is necessary to adjust for the severity of the patient’s illness. Should hospitals with poor results be publicly named? These are some of the hot topics in quality research today.^{1–3}

If you visit the handsome Playfair Library Hall of Old College, University of Edinburgh, you will see among the marble busts of 19th century professors and notables that of Sir James Young Simpson MD (1811–1870). Son of a baker in Bathgate Scotland, educated at Edinburgh, qualified as a surgeon at age 18, and elected to the Professorship of Midwifery there in 1840. In 1847 he was appointed “Physician Accoucheur to the Queen for Scotland”. He is remembered in Edinburgh today for his introduction of chloroform as an anaesthetic. Queen Victoria received it in April 1853 during childbirth.⁴ His collected published works fill several volumes. Of all this, our interest is in his forgotten comparative study of severity adjusted surgical mortality in 1869.

Simpson sent out survey questionnaires to practising country surgeons in England and Scotland. 374 replies were received. He asked how many amputations they performed, the type of amputation, and whether the patient lived or died. 2098 amputations were reported to him. He collected similar data from small and medium sized hospitals (3077 cases) and from 11 large hospitals (2089 cases) in England and Scotland.⁵

Severity of illness

Amputations were reported in four categories from thigh (the most severe condition), leg, arm and forearm (the least severe condition). Simpson showed a dramatic difference in mortality for these country doctors by case severity (table 1), with a 37 fold difference between the mortality following amputation of the forearm and the thigh. Note in table 1 that the sample sizes for the four types of amputation were all large. Outcome studies often have distributions that approximate the normal, which results in most observations being in the middle and a few at the highest and lowest tails. These high and low extremes are compared. Mortality differences are therefore based on a few observations out of many. Due to the sample sizes and large differences, Simpson’s risk adjustment is persuasive.

Experience of the surgeon

Controlling for case mix (type of amputation), Simpson compared mortality for these country surgeons by experience. The inexperienced surgeons were defined as having performed less than six amputations and more experienced surgeons had performed six or more amputations. Table 2 shows that experienced surgeons had a lower severity adjusted mortality rate for each level of severity.

Table 1 Percentage mortality by type of amputation: 374 country surgeons reporting 2098 cases in Scotland and England, 1869

Type of amputation	Mortality (%)	No of cases
Thigh	18.3	669
Leg	13.2	618
Arm	4.3	433
Forearm	0.5	378

Hospital size

Simpson collected amputation mortality data from some of the UK’s greatest large teaching hospitals (2089 cases) and from smaller hospitals (3077 cases) and compared amputation mortality by hospital size (table 3). The bigger the hospital, the worse the mortality. Table 3 does not adjust for case mix severity, but Simpson does this in his published report to show that case mix differences do not account for these mortality differences by hospital size. The best outcomes were from private country practice “with patients operated on in single or isolated rooms”.

Naming and blaming

The hospitals and their mortality rates are all named by Simpson. To pick one: table 4 shows the mortality for the great Royal Infirmary of Edinburgh associated with Simpson’s medical school. The morbidly curious scholar can read about the equally dismal outcomes at the famous St Bartholomew’s, Guys’, London, and St George’s hospitals. Compare the severity adjusted outcomes between tables 1 and 4 to see the good results in non-hospital care compared with big hospitals.

Simpson uses 40 pages answering criticisms of his study.⁶ Some of the issues raised were biased sampling of rural practitioners, recall bias, inadequate severity adjustment, and a lack of understanding of causation.

Table 2 Type of amputation, percentage mortality for inexperienced and experienced surgeons: 374 country surgeons reporting 2098 cases, 1869

Type of amputation	Inexperienced surgeons (<6 amputations) (n = 255)		Experienced surgeons (≥6 amputations) (n = 119)	
	No of cases	Mortality (%)	No of cases	Mortality (%)
Thigh	193	22.7	476	16.5
Leg	178	18.0	440	11.3
Arm	134	6.0	299	3.6
Forearm	124	0.8	154	0.4

Table 3 Hospital size and amputation mortality

Hospital size (no of beds)	No of amputations	Mortality (%)
300+	2089	41
201–300	803	28
101–200	1370	22
26–100	761	18
≤ 25	143	14
Country practice outside hospital	2098	11

Achievable results unachieved

This concept has been championed recently by John Williamson.⁷ Here is how Simpson presents this concept.

“Out of 2089 amputations in big urban hospitals 855 died; out of 2098 amputations in country practice 226 died; giving an excess to hospital practice of 629 deaths”

“This excess ... of 629 deaths in hospital practice as compared to rural practice—in our palatial hospitals as compared with our rural villages and cottages; in large wards as compared to isolated rooms—is certainly much greater and more pronounced than I myself expected ... But must the calling of this dismal death-roll still go unchallenged and unchecked? Shall this pitiless and deliberate sacrifice of human life to conditions which are more or less preventable be continued or arrested? Do not these terrible figures plead eloquently and clamantly for a revision and reform of our existing hospital system?”

Process and outcome

It is not sufficient to observe outcome differences. To correct them we must know the process that leads to their outcomes—the cause and effect. Simpson, like Nightingale,⁸ attributed hospital mortality to overcrowding of patients and associated unsanitary conditions. This was referred to as “hospitalism” and thought to be due to bad air or “miasmas”. The acceptance of the germ theory of infection was to come later. With 140 years of hindsight, Simpson’s study seems plausible with our current understanding of hospital infection and its control. Semmelweis found out how to reduce this mortality in obstetrics without the understanding of germ theory.⁹ A policy result of Simpson’s study

Table 4 Mortality rate by type of amputation, Royal Infirmary Edinburgh, 1859–68

Type of amputation	No of cases	Mortality (%)
Thigh	199	47.2
Leg	86	44.2
Arm	28	53.6
Forearm	58	20.7

was the British “cottage hospital movement” of the late 1800s which promoted the creation of small rural hospitals.

Today’s surgical outcome studies show that high volume larger hospitals often have better outcomes. Simpson found the opposite. This tells us that a simple theory of hospital size and good outcomes is inadequate, and we must look for better theories to explain this relationship across centuries.

Simpson died a hero. An estimated 30 000 people attended his funeral in Edinburgh in 1870.
